ABSTRACT

We propose an extension of the existing information criterion-based structural break identification approaches. The extended approach helps identify both *pure structural change (break)* and *partial structural change (break)*. A pure structural change refers to the case when breaks occur simultaneously in all parameters of regression equation, whereas a partial structural change happens when breaks occur in some parameters only. Our approach consistently outperforms other well known approaches. We also extend the simulation studies of Bai and Perron (2006) and Hall et al. (2013) by including more general cases. This provides more comprehensive results and reveals the cases where the existing identification approaches lose power, which should be kept in mind when applying them.

Keywords: Identification of structural breaks, partial structural change, pure structural change, information criterion, Monte Carlo simulation.

Journal of Economic Literature classification: C01, C1, C51, C52.

Partial Structural Break Identification

ABSTRACT

We propose an extension of the existing information criterion-based structural break identification approaches. The extended approach helps identify both *pure structural change (break)* and *partial structural change (break)*. A pure structural change refers to the case when breaks occur simultaneously in all parameters of regression equation, whereas a partial structural change happens when breaks occur in some parameters only. Our approach consistently outperforms other well known approaches. We also extend the simulation studies of Bai and Perron (2006) and Hall et al. (2013) by including more general cases. This provides more comprehensive results and reveals the cases where the existing identification approaches lose power, which should be kept in mind when applying them.

Keywords: Identification of structural breaks, partial structural change, pure structural change, information criterion, Monte Carlo simulation.

Journal of Economic Literature classification: C01, C1, C51, C52.

1 Introduction

Structural breaks have been observed in many economic and financial time series, see Stock and Watson (1996) among others. It is well established that ignoring these breaks has undesirable consequences on time series analysis. In particular, authors such as Clements and Hendry (1998, 1999) consider the ignorance of structural breaks as a main reason of forecast failure. Hence the importance of providing robust statistical procedure for detecting and estimating the number of breaks cannot be overemphasized.

Several approaches have been proposed to detect structural breaks in economic and financial time series. Andrews (1993) and Bai and Perron (1998) introduced statistical testing procedures to investigate the presence and timing of change when one or more breaks occur within the available time series data. Perron and Qu (2006) extended these results to the case where arbitrary linear restrictions on the coefficients are available a priori. Another class of approaches are based on information criteria. Yao (1988), Liu et al. (1997), and Zhang and Siegmund (2007) considered Bayesian information criterion (BIC) of Schwarz (1978), whereas Ninomiya (2005) used Akaike's information criterion (AIC) of Akaike (1973). In addition, Bai (2000) established conditions under which an information criterion is consistent for estimation of the number of breaks in vector autoregressions with martingale difference sequence errors. Finally, recently Chen, Gerlach, and Liu (2011) have used a Bayesian computational method to identify the locations of structural breaks in the context of time-varying regression model and in the presence of heteroskedasticity and autocorrelation.

In this paper, we extend the existing information criterion-based approaches to identify both pure and partial structural changes. A pure structural change refers to the case when breaks occur simultaneously in all parameters of regression equation, whereas a partial structural change refers to the case when breaks occur in some parameters only. One drawback of the existing approaches is that they assume pure (simultaneous) structural breaks only, although this may not be the case in reality. For example, if a monetary policy measure is included as one of the regressors and one wants to examine the effect of changes in this measure on a dependent macro variable, there is no reason to assume that other regressors will also experience a structural break at the same time. If breaks occur only in some of the regressors, as explained in Section 3, the existing information criterion-based approaches will underestimate the number of breaks. Our extension aims to address this problem of the existing approaches and detect partial structural breaks as well as pure structural breaks.

Another contribution of this paper is that we provide a Monte Carlo simulation study which compares the performance of our approach with the exiting ones for a large set of data-generating processes that represent different contexts encountered in practice. We extend the simulation studies of Bai and Perron (2006) and Hall et al. (2013) by including more general cases, especially the cases where break detection becomes difficult. This provides more comprehensive results and reveals the potential areas where the

existing methods lose their power. Simulation results show that our approach consistently outperforms other well known approaches such as the ones introduced by Yao (1988) and Bai and Perron (1998).

The rest of the paper is organized as follows. The framework that defines the regression model with multiple breaks and a general procedure that identifies these breaks is introduced in Section 2. Section 3 provides a brief summary of the existing information criterion-based approaches and discusses our approach for detecting partial breaks. In Section 4, we use Monte Carlo simulations to investigate the performance of our approach by comparing it with the existing ones. Section 5 concludes.

2 Framework

We consider the following N -variable linear system with K breaks

$$y_t = X_t \beta_k + e_t, \text{ for } \tau_{k-1} \leq t < \tau_k, \text{ with } k = 1, \dots, K+1, \quad (1)$$

where $X_t = [1 \ x_{1t} \ \dots \ x_{Nt}]$ is a vector of covariates, $\beta_k = [\beta_{0k} \ \dots \ \beta_{Nk}]'$ is a vector of parameters of interest that are subject to multiple structural breaks, and e_t is an error term. K breaks means that we are in presence of $K+1$ regimes that are defined by the time set $\{\tau_0 = 1, \dots, \tau_{K+1} = T\}$ within the whole sample of size T . The problem now is to identify the number (K) and timing (τ_k) of the breaks. A general procedure for this consists of the following two steps:

Identification of the timing of breaks: The first step is to find τ_k , for $k = 1, \dots, K$, that minimize the residual sum of squares (RSS). Formally, we select τ_1, \dots, τ_K that minimize the RSS:

$$\{\hat{\tau}_1, \dots, \hat{\tau}_K\} = \underset{\tau_1, \dots, \tau_K}{\operatorname{argmin}} \left\{ RSS_K = \sum_{k=1}^{K+1} RSS_k \right\}, \quad (2)$$

where

$$RSS_k = \sum_{t=\tau_{k-1}+1}^{\tau_k} (y_t - X_t \hat{\beta}_k)^2, \text{ for } k = 1, \dots, K+1. \quad (3)$$

This is repeated for $K = 0, \dots, K_{max}$, a pre-specified maximum number of breaks. As noted by Bai and Perron (2006), there are $T(T-1)/2$ possible regimes within the sample.¹ Therefore, the global minimum of the problem in (2) can be found efficiently as follows: 1) calculate RSS_k for all the possible regimes; 2) for a given set of τ_1, \dots, τ_K , choose the corresponding RSS_k 's and simply add them up to obtain RSS .

Determination of the number of breaks: The second step is to determine the number of breaks by comparing the global minima for $K = 1, \dots, K_{max}$. This normally consists of using a statistical test-based procedure such as the one in Bai and Perron (1998, 2003, 2006) and Perron and Qu (2006) or an information criterion-based approach as in Yao (1988), among others.

¹For a start time $t = 1, \dots, T-1$, there are $T-t$ ending times, which gives total $T(T-1)/2$ regimes.

3 Information criterion-based approaches

3.1 Brief summary of the existing approaches

Several information criterion-based identification methods have been proposed to determine the number of breaks. The first and well known approach was introduced by Yao (1988). He shows that when the residuals e_t in (1) are i.i.d. normal, breaks in mean can be identified using the Bayesian information criteria (BIC) of the form:

$$BIC(K) = T \log \frac{RSS_K}{T} + ((N+1)(K+1) + K) \log T, \quad (4)$$

where RSS_K is the residual sum of squares at its minimum as defined in (2), N is the number of covariates in the regression equation (1), K is the number of breaks, and T is the sample size. Yao (1988) suggests to choose the number of breaks K that has the minimum BIC, i.e.,

$$\hat{K} = \underset{K}{\operatorname{argmin}} BIC(K). \quad (5)$$

Liu, Wu and Zidek (1997) have also used a BIC for the identification of number of breaks. Their approach, however, appears to underperform in the simulation analyses reported in Bai and Perron (2006) and Hall et al. (2013), and will not be considered further in this paper.

More recently, Hall et al. (2013) proposed an alternative approach where the penalty for the breaks is $3K$ instead of K . Their information criteria has the form:

$$BIC(K) = T \log \frac{RSS_K}{T} + ((N+1)(K+1) + 3K) \log T. \quad (6)$$

With the penalty term $3K$, their approach is more conservative and is likely to underestimate the number of breaks compared to Yao (1988) approach.

Finally, Bai and Perron (1998, 2003, 2006) proposed sequential statistical procedures to determine the number of breaks. Perron and Qu (2006) have extended these results to the case where arbitrary linear restrictions on the coefficients are available a priori. For more details about these statistical procedures, the reader is referred to Bai and Perron (1998, 2003, 2006) and Perron and Qu (2006) or Hall et al. (2013) for a summary.

3.2 Extended approach

One drawback of Yao (1988) and other existing approaches is that they assume pure structural changes in all the regressors. However, this is not necessarily the case in many circumstances. For example, if a monetary policy measure is included as one of the regressors and we want to examine the effect of changes in this measure on a dependent variable, there is no reason to assume that other regressors will experience structural breaks at the same time. If a break occurs only in some of the regressors, as illustrated in the

following example, the term $(K + 1)(N + 1)$ in (4) and (6) will impose too severe penalty, and therefore it will result in underestimation of the number of breaks in finite samples.

Our extension of the existing approaches aims to address this issue by taking partial breaks into account. Note that the BIC formula in (4) can be viewed as the BIC of a dummy variable regression equation with unknown K breaks. For example, consider a bivariate system with one break at time τ_1 . A corresponding dummy variable regression equation will have the form

$$\begin{bmatrix} y_1 \\ \vdots \\ y_{\tau_1} \\ y_{\tau_1+1} \\ \vdots \\ y_T \end{bmatrix} = \begin{bmatrix} 1 & x_1 & 1 & x_1 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_{\tau_1} & 1 & x_{\tau_1} \\ 1 & x_{\tau_1+1} & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_T & 0 & 0 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \end{bmatrix} + \begin{bmatrix} e_1 \\ \vdots \\ e_{\tau_1} \\ e_{\tau_1+1} \\ \vdots \\ e_T \end{bmatrix}.$$

The BIC of this regression is the same as the one in (4). Now, if the break occurs only in x , a corresponding dummy variable regression equation will have the form

$$\begin{bmatrix} y_1 \\ \vdots \\ y_{\tau_1} \\ y_{\tau_1+1} \\ \vdots \\ y_T \end{bmatrix} = \begin{bmatrix} 1 & x_1 & x_1 \\ \vdots & \vdots & \vdots \\ 1 & x_{\tau_1} & x_{\tau_1} \\ 1 & x_{\tau_1+1} & 0 \\ \vdots & \vdots & \vdots \\ 1 & x_T & 0 \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \end{bmatrix} + \begin{bmatrix} e_1 \\ \vdots \\ e_{\tau_1} \\ e_{\tau_1+1} \\ \vdots \\ e_T \end{bmatrix}.$$

In this case, the correct BIC is given by:

$$BIC(K) = T \log \frac{RSS_K}{T} + (N + 1 + NK + K) \log T,$$

where RSS_K is the residual sum of squares from the above dummy variable regression equation. Similarly, we can construct a dummy variable regression for a break in the intercept only and obtain the corresponding BIC. In general, for a system of $N + 1$ regressors including constant, there are \mathcal{C}_j^{N+1} possible combinations of partial breaks in j regressors out of $N + 1$ regressors. Therefore, the total number of potential partial breaks becomes²

$$D = \mathcal{C}_1^{N+1} + \dots + \mathcal{C}_{N+1}^{N+1}.$$

The BIC of case d , $d = 1, \dots, D$, can be calculated using the following formula

$$BIC(K, d) = T \log \frac{RSS_K(d)}{T} + (N + 1 + nK + K) \log T \quad (7)$$

²When there are more than one break, we assume that all breaks occur in the same regressors.

where n and $RSS_K(d)$ are respectively the number of regressors experiencing breaks and the residual sum of squares of the corresponding dummy variable regression in case d .³ The number of breaks is determined by choosing K that minimizes the BIC in all cases. That is:

$$\hat{K} = \underset{K}{\operatorname{argmin}} BIC(K, d), \quad \text{for } d = 1, \dots, D. \quad (8)$$

When only $n < N$ regressors experience breaks, it is sensible to adjust the penalty term proportionately to the ratio n/N . In this case, Equation (7) needs to be modified as follows:

$$BIC(K, d) = T \log \frac{RSS_K(d)}{T} + \left(N + 1 + nK + \frac{n}{N}K \right) \log T. \quad (9)$$

The following proposition establishes the consistency of the estimation of the number of breaks K based on the minimization problem defined in (8), where $BIC(K, d)$ is given by (7) or (9). The assumptions needed to derive Proposition (1) are similar to the ones considered in Yao (1988) and Liu, Wu and Zidek (1997); see for example Assumptions 4.1-4.1' in Liu, Wu and Zidek (1997).

Proposition 1 *Assume that $K^0 \leq K_{max}$, $\beta_k^0 \neq \beta_{k+1}^0$ for $1 \leq k \leq K^0$, with superscript 0 denoting the true parameters, and τ_k/T for $1 \leq k \leq K^0$ converges to λ_k as $T \rightarrow \infty$ for some $0 < \lambda_1 < \dots < \lambda_{K^0} < 1$. Then,*

$$\Pr \left(\hat{K} = K^0 \right) \rightarrow 1 \quad \text{as } T \rightarrow \infty.$$

See Appendix A for proof. Proposition 1 is valid for both the BIC in Equation (7) or its modified version in Equation (9).

We also consider Hannan & Quinn criterion (HQC) of the form

$$HQC(K) = T \log \frac{RSS_K}{T} + 2((N + 1)(K + 1) + K) \log(\log T), \quad (10)$$

and its extensions.⁴ As $2 \log(\log T) < \log T$ for $T > 2$, HQC based approaches are expected to overfit compared to BIC based approaches.

Through various simulations, we observe that information criterion-based methods often select zero break when the true number of breaks is greater than zero. Furthermore, in many cases, we find that the BIC of the true number of breaks, K , is often a local minimum, i.e.,

$$BIC(K) < \min(BIC(K + 1), BIC(K - 1)).$$

Based on this observation, we further improve our approach by adding the following procedure (henceforth, referred to as the *modification*):

³Equation (7) is an extension of Yao's (1988) model. Hall et al. (2013) model can also be extended in the same manner by replacing K in the last term of equation (7) with $3K$.

⁴We thank the anonymous referee for suggesting this.

1. Find K 's such that

$$BIC(K) < \min(BIC(K+1), BIC(K-1)), \quad K > 0.$$

2. If there exist at least one K that satisfy the above condition, choose K that has the minimum BIC as the number of breaks.
3. Otherwise, set the number of breaks to zero.

4 Monte Carlo simulation

In this section, we use Monte Carlo simulation to compare the performance of our approaches and the existing ones for various data generating processes (DGPs) that represent different contexts encountered in practice. Our DGPs are based on those of Hall et al. (2013) and Bai and Perron (2006), but we consider additional DGPs that extend the previous ones to highlight more general cases where identification approaches could lose power. We compare 12 approaches: 8 extensions and 4 existing models, as listed in Table 1. 10% trimming value is used in all models, and 10% statistical significance level is applied for Bai and Perron (2006) approaches.

Table 1: Comparison Models

Model	Description
B1	Yao (1988)
B1A	Extension of Yao (1998): Partial breaks (BIC defined in (7))
B1B	B1A with the modification
B1C	Extension of Yao (1998): Partial breaks and fractional penalty (BIC defined in (9))
B1D	B1C with the modification
B3	Hall et al. (2013)
B3A	Extension of Hall et al. (2013): Partial breaks
HQ	HQC defined in (10)
HQA	Extension of HQC: Partial breaks
HQB	HQA with modification
BP	Bai and Perron (2006) without correction for heteroscedasticity and serial correlation
BPH	Bai and Perron (2006) with correction for heteroscedasticity and serial correlation using HAC estimator

We use two sample sizes $T = 120$ and 240 as in Bai and Perron (2006). However, for the sake of saving space, we only report the results for $T = 120$. The results for $T = 240$ are qualitatively similar to those obtained for $T = 120$ and are available upon request. We consider the cases of $K = 0, 1$, and 2 , and assume that the breaks occur at same intervals, *i.e.*, $t = 60$ for $K = 1$ and $t = \{40, 80\}$ for $K = 2$. For the number of regressors, we use one or two independent variables. We have considered up to three breaks and four independent variables, but decided to exclude them from the paper as the results for those cases can be generally extrapolated from the results reported here. We run 1,000 simulations to evaluate the performances of different approaches. The performance is measured by the probability of capturing the true number of breaks. The rest of the section describes the DGPs considered in our analysis.

4.1 Data generating processes

4.1.1 No Breaks

For the cases of no break, we employ the same data generating processes as in Hall et al. (2013) with minor modifications. These DGPs are described below:

$$\text{DGP1 } y_t = e_t$$

$$\text{DGP2 } y_t = x_t + e_t$$

$$\text{DGP3 } y_t = 0.5y_{t-1} + e_t$$

$$\text{DGP4 } y_t = u_t, \text{ with } u_t = 0.5u_{t-1} + e_t$$

$$\text{DGP5 } y_t = u_t, \text{ with } u_t = e_t + 0.5e_{t-1}$$

$$\text{DGP6 } y_t = u_t, \text{ with } u_t = e_t - 0.5e_{t-1}$$

$$\text{DGP7 } y_t = 1 + x_{1t} + x_{2t} + e_t$$

$$\text{DGP8 } y_t = 1 + x_{1t} + x_{2t} + u_t, \text{ with } u_t = 0.5u_{t-1} + e_t,$$

where y_t is the dependent variable that we generate from e_t and x_{it} , for $i = 1, 2$, with $e_t \sim N(0, 1)$ and $x_{it} \sim N(1, 1)$. For more details about these DGPs, the reader is referred to Hall et al. (2013).

4.1.2 Multiple Breaks

We now consider DGPs with multiple breaks. These DGPs basically have either of the two forms:

$$y_t = X_t\beta_k + e_t, \text{ with } e_t \text{ i.i.d (hereafter MA(0))} \quad (11)$$

$$y_t = X_t\beta_k + u_t, \text{ with } u_t \sim \text{MA}(1): u_t = 0.5u_{t-1} + e_t, \quad (12)$$

where X_t is a vector of covariates. In (11), the residual is assumed to be serially uncorrelated, whereas it is serially correlated in (12). For each case, twenty one DGPs are considered as summarized in Table 2.

Both Bai and Perron (2006) and Hall et al. (2013) assume that $e_t \sim N(0, 1)$ and $x_{it} \sim N(1, 1)$. However, break detection becomes more challenging when the expected value of x_{it} is zero. This is because when the

expected value is zero, a break in x_{it} does not automatically induce a break in the constant term. Another case where the detection is likely to fail is when the variance of the residual is larger than the variance of the regressors, i.e., when the regression has a low goodness of fit. We consider these cases in our simulation analysis by assuming four cases for each DGP:

$$\text{CASE I: } x_{it} \sim N(1, 1), \quad e_t \sim N(0, 1)$$

$$\text{CASE II: } x_{it} \sim N(0, 1), \quad e_t \sim N(0, 1)$$

$$\text{CASE III: } x_{it} \sim N(1, 1), \quad e_t \sim N(0, 2)$$

$$\text{CASE IV: } x_{it} \sim N(0, 1), \quad e_t \sim N(0, 2).$$

Therefore, we have a total of 200 DGPs ($50 \text{ DGPs} \times 4 \text{ cases}$) in the simulation analysis.

4.2 Simulation results

The results of the Monte Carlo simulation study can be found in Tables 3 to 7. Tables 3 to 6 report the probability of correct identification for each DGP in CASE I - IV, respectively, and Table 7 provides the average probabilities across DGPs in each case. Our discussion will be mainly based on CASE I.

The first thing to note is that both extensions B1A and B3A significantly improve the performances of their counterparts B1 and B3. On average, B1A identifies breaks correctly with a probability of 57% for CASE I, 6% higher than B1. B3A also improves the performance of B3 by 6% (44% vs 38%). Furthermore, note that the existing approaches perform very poorly when the breaks occur only in some parameters. This is clear if we compare DGPs 9 and 10 with 11, or DGPs 15, 16, and 17 with 18. Break detection becomes challenging when x_{it} have zero mean and it becomes more so if the constant term remains the same. However, when partial breaks are accounted for, the performance improves significantly and the detection probability remains relatively high even when x_{it} have zero mean. For example, if we compare DGP 18 of CASE I with that of CASE II, the correct detection probability of B1 drops from 98% to 74%, and for DGP 17 in which the constant remains the same, it is only 69% for CASE I and 50% for CASE II. On the contrary, the corresponding values of B1A and B1C are respectively 95%, 82%, 96%, and 71%, and 88%, 81%, 91%, and 79%.

For most DGPs, accounting for partial breaks turns out to improve break detection. Some of the exceptions where the performance deteriorates are found in DGPs 8, 14, and 22. These DGPs all have serially correlated error terms. In general, the extended approaches are less effective when the error term is serially correlated. Still, this can be largely avoided by employing the modification as can be seen from the results of B1B. Overall, B1B improves over B1A.

The approaches B1C and B1D that use fractional penalty term as in Equation (9) tend to slightly overestimate the number of breaks compared to their counterparts B1A and B1C. This results in much improved performance when there exist breaks at the cost of underperformance when there is no break

Table 2: Data-generating processes

DGP42	DGP50	1	1	1	1	1.5	0.5	1	1 1

Note: This table summarizes the values of the coefficients (including the constant) of the data generating processes (DGPs) that we consider in the simulation study to compare different structural break identification approaches. We consider up to two breaks and two independent variables. “ $e_t \sim \text{MA}(0)$ ” indicates that the error term in the regression is an MA(0) or without correlation, and “ $u_t \sim \text{MA}(1)$ ” indicates that the error term is an MA(1).

(DGPs 1 to 8). Nevertheless, the overall performance improvement is significant and B1D turns out to perform best among the models in our experiment.

As expected, the HQC based approaches over-fit compared to the BIC based approaches, resulting in underperformance for no break DGPs and outperformance for DGPs with breaks. On average, HQ outperforms B1, while HQA and HQB perform similar to B1A and B1B. We also considered HQC based approaches with fractional penalty. But the results were not promising and are not reported in this paper.

It is important to note that, in some circumstances, the detection methods have practically no power. For instance, for DGPs 25, 35, and 42, both B1 and B3 have almost zero probability of correct identification, less than 10% for BP, and around 15% for BPH. B1A and B1B do improve the performance of B1 for these DGPs, but the performance is still weak. As shown in the second column ($\Delta\tau$) of the tables, which is the average of $|\tau_k - \hat{\tau}_k|$, low detection power is generally associated with a large estimation error of τ_k .⁵ This means that even if the number of breaks are correctly identified, the timing of the break is likely to be incorrect. Recall that τ_k are determined in the first step of identification by minimizing RSS. Since this step is common to all methods, any improvement in the number of breaks determination methods has a certain limit. Therefore, when the estimation error of τ_k is large, a more fundamental change is required to improve break identification. For example, a different estimator other than OLS could be considered for the estimation of β_k in (1). We leave this topic for future research.

Break detection also becomes difficult when the R^2 of the regression is small. This can be seen by comparing CASE I with CASE III and CASE II with CASE IV. Overall, if R^2 is small, none of the tested approaches are reliable.

Other observations include the followings: Hall et al. (2013) approach seems to be too conservative, therefore works well when there is no break but underestimates the number of breaks when $K > 0$. BPH does not perform better than BP for MA(1) DGPs and indeed the results are often contrary.

Finally, we should mention that the values reported in the above discussed tables correspond to the probabilities of correctly identifying the number of breaks in the models and cases discussed in Section 4.1. In the presence of partial break models, our statistical procedure does search over all possible locations (intercept and slopes) of the breaks. For example, in the case of a model with an intercept, single regressor, and one break, our procedure does calculate and compare the information criteria from pure structural change; partial structural change in the intercept; and partial structural change in the slope. However, one may ask if the proposed procedure also detects the correct model that corresponds to the correct location of the break(s). To answer this question, we ran additional simulations where we look at the probability of identifying the correct models.⁶ These new simulations are added in Table 8 which reports the probability

⁵ $\Delta\tau$ is determined by Equation (2) of the break timing identification step, and therefore is the same for all the approaches.

⁶We thank very much an anonymous referee for his/her remark which led to these additional simulations.

of correctly specifying the true partial break model, for some of the models and cases discussed in Section 4.1. That is, the probability that our procedure correctly identifies the covariates (including intercept) that are subject to breaks when the number of breaks has been correctly identified. As it can be seen in Table 8, the probability of correctly identifying the covariates that experience breaks is high in all models under consideration, especially when the probability of correct identification of the number of breaks is high. However, for those DGPs for which the number of breaks is difficult to identify, the probability of correctly identifying the true partial break model is low.

5 Conclusion

We have proposed extensions of the existing information criterion-based structural break identification approaches that allow us to identify both pure and partial structural breaks. We provide a correct BIC formula for partial breaks and consider all the possible partial breaks when determining the number of breaks. We also introduce a modified method to further improve the break identification. A Monte Carlo simulation study with a large set of DGPs shows that the extended approaches consistently outperform other well known approaches such as the ones introduced by Yao (1988), Bai and Perron (1998), and Perron and Qu (2006). Overall, the extension of Yao (1988) model with fractional penalty term and the modification performs best among the models tested in our study. We also find that when the goodness of fit of the regression is low, all the approaches tested in this paper become unreliable. Thus, we suggest to reconsider using a break detection method when the R^2 of a regression is low.

A Proof of Proposition 1

Proof. Our approach is similar to those that appear in Yao (1988) and Liu et al. (1997), with the exception that, in our case, we need to select K across different values of d or the combinations of regressors

experiencing breaks; please see Section 3.2 for more details. The total number of combinations is equal to $D = \mathcal{C}_1^{N+1} + \dots + \mathcal{C}_{N+1}^{N+1}$, where $N + 1$ is the number of regressors including the constant.

Pointwise consistency or the consistency of our approach for a given d can be proven using almost the same arguments made in the proof of Yao's (1988) Proposition in page 182 or those in the proof of Theorem 4.1 of Liu et al. (1997). Thereafter, the uniform consistency or the consistency across different d can be deduced from the pointwise consistency.

We first start with the pointwise consistency. Consider similar assumptions to those in Yao (1988) and Liu et al. (1997) (see, for example, Assumptions 4.1-4.1' in Liu, Wu and Zidek (1997)) and assume that $\beta_k^0(d) \neq \beta_{k+1}^0(d)$ for $1 \leq k \leq K^0(d) \leq K_{max}$ with superscript 0 denoting the true parameters of the d -th case, and $\tau_k(d)/T$ for $1 \leq k \leq K^0(d)$ converges to $\lambda_k(d)$ as $T \rightarrow \infty$ for some $0 < \lambda_1(d) < \dots < \lambda_{K^0(d)}(d) < 1$. Here, we implicitly assume that for each d there is a true number of breaks that we denote by $K^0(d)$, but we assume the same upper bound for K across different d , which we denote by K_{max} . Under the above assumptions, the pointwise consistency can be obtained in two steps. In the first step, we show that

$$\Pr \left(\hat{K}(d) \geq K^0(d) \right) \rightarrow 1, \text{ as } T \rightarrow \infty,$$

where $\hat{K}(d)$ is the estimated number of breaks obtained by minimizing BIC for a given d , i.e.,

$$\hat{K}(d) = \underset{K}{\operatorname{argmin}} BIC(K, d).$$

In the second step, we show that, for $K^0(d) < K \leq K_{max}$,

$$\Pr \left(BIC(K, d) - BIC(K^0(d), d) > 0 \right) \rightarrow 1, \text{ as } T \rightarrow \infty.$$

Hence,

$$\Pr \left(\hat{K}(d) = K^0(d) \right) \rightarrow 1, \text{ as } T \rightarrow \infty.$$

Now, to show $\Pr \left(\hat{K}(d) \geq K^0(d) \right) \rightarrow 1$ as $T \rightarrow \infty$, we use the results in Lemma 2 and 3 of Yao (1988); see also Lemma 5.4 of Liu et al. (1997). Proofs of Lemma 2 and 3 of Yao (1988) in our context can be obtained using similar arguments to the ones used in Yao (1988), hence they are omitted. The following can be immediately implied from Lemma 2 of Yao (1988): as $T \rightarrow \infty$,

$$0 \leq \frac{1}{T} \sum_{t=1}^T e_t^2(d) - \hat{\sigma}_{K^0}^2(d) = O_p \left(T^{-1} \log T \right),$$

where $e_t(d)$ is the error term in the dummy variable regression of the case d , and

$$\hat{\sigma}_{K^0}^2(d) = \frac{RSS_{K^0}(d)}{T} = \sum_{k=1}^{K^0(d)+1} \sum_{t=\tau_{k-1}(d)+1}^{\tau_k(d)} (y_t - X_t \hat{\beta}_k(d))^2.$$

From Lemma 3 of Yao (1988), for $K < K^0(d)$, there exists $\epsilon > 0$ such that

$$\Pr \left(\hat{\sigma}_K^2(d) > \sigma_0^2(d) + \epsilon \right) \rightarrow 1, \text{ as } T \rightarrow \infty,$$

where $\sigma_0^2(d)$ is the true variance of the error term $e_t(d)$. Thus, using the results of Lemma 2 and 3 and the Schwartz's criterion, we get

$$\Pr \left(\hat{K}(d) \geq K^0(d) \right) \rightarrow 1, \text{ as } T \rightarrow \infty. \quad (13)$$

To show the final result, $\Pr \left(\hat{K}(d) = K^0(d) \right) \rightarrow 1$, as $T \rightarrow \infty$, we need Lemma 5 of Yao (1988). Again, proof of Lemma 5 of Yao (1988) in our context can be obtained using similar arguments to the ones used in Yao (1988), hence it is omitted. Lemma 5 states that for every K , $K^0(d) < K \leq K_{max}$, and for any $\epsilon > 0$, with probability approaching 1,

$$0 \leq \sum_{t=1}^T e_t^2(d) - T \hat{\sigma}_K^2(d) \leq \{ \epsilon + 2 (K - K^0(d) - 1) (1 + \epsilon) \} \sigma_0^2(d) \log T,$$

where

$$\hat{\sigma}_K^2(d) = \frac{RSS_K(d)}{T} = \sum_{k=1}^{K(d)+1} \sum_{t=\tau_{k-1}(d)+1}^{\tau_k(d)} (y_t - X_t \hat{\beta}_k(d))^2.$$

From the result of Lemma 5, for the modified Schwartz's criterion defined in Equation (7),

$$\begin{aligned} & 2 \{ BIC(K, d) - BIC(K^0(d), d) \} \\ \geq & T \log \frac{RSS_K(d)}{T} - T \log \frac{\sum_{t=1}^T e_t^2(d)}{T} + 2 \{ nK + K - nK^0(d) - K^0(d) \} \log T \\ = & T \log \left\{ 1 - \frac{\left\{ \sum_{t=1}^T e_t^2(d) - T \hat{\sigma}_K^2(d) \right\}}{\sum_{t=1}^T e_t^2(d)} \right\} + 2 \{ nK(d) + K(d) - nK^0(d) - K^0(d) \} \log T \\ \geq & T \log \left\{ 1 - \{ \epsilon + 2 (K - K^0(d) - 1) (1 + \epsilon) \} \sigma_0^2(d) \log T / \{ T (\sigma_0^2(d) - \epsilon) \} \right\} \\ & + 2 \{ nK + K - nK^0(d) - K^0(d) \} \log T, \end{aligned}$$

which, using $\log(1 - x) > (1 + \epsilon)(-x)$ for small x , is greater than

$$\begin{aligned} & - (1 + \epsilon) \{ \epsilon + 2 (K - K^0(d) - 1) (1 + \epsilon) \} \sigma_0^2(d) \log T / \{ T (\sigma_0^2(d) - \epsilon) \} \\ & + 2 \{ nK + K - nK^0(d) - K^0(d) \} \log T, \text{ for large } T. \end{aligned} \quad (14)$$

Since the term (14) is positive for sufficiently small $\epsilon > 0$, we have $\Pr (BIC(K, d) - BIC(K^0(d), d) > 0) \rightarrow 1$.

Hence the pointwise consistency,

$$\Pr \left(\hat{K}(d) = K^0(d) \right) \rightarrow 1, \text{ as } T \rightarrow \infty.$$

The argument above also holds using Equation (9) instead of (7).

Now, because the inequality $BIC(K, d) > BIC(K^0(d), d)$ holds for all d , we have

$$\min \{ BIC(K, d), \text{ for } d = 1, \dots, D \} > \min \{ BIC(K^0(d), d), \text{ for } d = 1, \dots, D \}.$$

Thus, if we assume that the global minimum of BIC, $\min \{BIC(K, d), \text{ for } d = 1, \dots, D\}$, corresponds to a combination d^0 (in this paper, d is not considered as random and the focus is only on the selection of K), then

$$BIC(K, d^0) > BIC(K^0(d^0), d^0) \text{ for } K^0(d^0) < K \leq K_{max}.$$

In addition, because the result in (13) holds for all d , it also holds for $d = d^0$. Hence,

$$\Pr \left(\hat{K}(d^0) = K^0(d^0) \right) \rightarrow 1 \text{ as } T \rightarrow \infty,$$

which completes the proof of Proposition 1. ■

Note: This table summarizes the performance of the structural break identification approaches for CASE I. The approaches are described at the beginning of Section 4, and the DGPs and the distribution assumption of CASE I are described in Section 4.1. The figures in columns 3 to 9 are the probability of correct detection in percentage. “ $\Delta\tau$ ” is the average distance between the true break dates and the estimated break dates.

Note: This table summarizes the performance of the structural break identification approaches for CASE II. The approaches are described at the beginning of Section 4, and the DGPs and the distribution assumption of CASE II are described in Section 4.1. The figures in columns 3 to 9 are the probability of correct detection in percentage. “ $\Delta\tau$ ” is the average distance between the true break dates and the estimated break dates.

K=1, N=1, $u_t \sim \text{MA}(1)$	25	27	31	24	33	9	13	19	19	23	35	22
K=1, N=2, $e_t \sim \text{MA}(0)$	7	26	25	46	46	0	1	25	45	44	25	35
K=1, N=2, $u_t \sim \text{MA}(1)$	21	27	31	23	32	6	13	21	20	29	33	26
K=2, N=1, $e_t \sim \text{MA}(0)$	1	2	3	10	10	0	0	9	16	19	1	6
K=2, N=1, $u_t \sim \text{MA}(1)$	17	25	26	26	31	2	3	23	25	30	17	5
K=2, N=2, $e_t \sim \text{MA}(0)$	0	2	3	14	14	0	0	7	20	21	3	10
K=2, N=2, $u_t \sim \text{MA}(1)$	9	24	25	25	30	0	3	22	27	32	16	10
All DGPs except K=0	9	18	19	24	27	2	4	18	25	29	17	16
All DGPs	21	27	28	31	33	17	18	25	29	31	27	27

Note: This table provides the mean probability of correct identification for the sub-samples defined in the first column. For example, “K=1, N=1, $e_t \sim \text{MA}(0)$ ” means the DGPs with one break, one covariate, and uncorrelated error terms.

Table 8: Probability of correct identification of partial breaks

	BREAKS			CASE I				CASE IV			
	C	X_1	X_2	B1A	B1C	B3A	HQA	B1A	B1C	B3A	HQA

Note: This table provides the probability of correct partial break identification for some selected models and cases. The columns under “BREAKS” indicate the variables subject to breaks (denoted by 1). The figures under a model are the probability that the model correctly identifies the variables subject to breaks when the number of breaks has been correctly identified. Breaks in constant are ignored in determining correct identification: *e.g.*, for DGP11 (where both the constant and X_1 are subject to breaks), the case when the constant and X_1 are identified to experience breaks and the case when only X_1 is identified to experience breaks are both considered to be correct identification.
